

1 Supplemental Information

2 Data

3 Forest cover in the year 2000 was estimated by applying a 50% threshold to the Percent Tree Cover Layer
4 of the 500 m Moderate Resolution Imaging Spectroradiometer (MODIS)-based Vegetation Continuous
5 Fields (VCF) product for the year 2000 (Hansen et al, 2003). The 50% threshold was selected to
6 distinguish mature forest from agricultural fallows using high-resolution, Landsat-based forest cover
7 maps for parts of Indonesia. This threshold has been applied by similar analyses in other tropical regions
8 (Leimgruber et al 2005; Harper et al 2007; Killeen et al 2007).

9 Our dependent variable, percent deforestation for the period 2000-2005, was derived by rescaling rates of
10 deforestation from data on the distribution of deforestation (tree cover loss estimates from the 463 m
11 MODIS VCF product; Hansen et al. 2008) upward by a factor of 2.147 to match data on the total rate of
12 deforestation (derived from analysis of a stratified, random sample of 77 18.5km x 18.5km blocks of 28.5
13 m resolution Landsat images; Hansen et al 2008; Hansen et al 2009). An alternative data set on forest
14 cover loss (Miettenen, 2011) was explored in a sensitivity analysis (Table SI9).

15 Our primary explanatory variable, net present potential gross agricultural revenue, was obtained from
16 Naidoo and Iwamura (2007). In this 5' data set the annual potential gross agricultural revenue in 2000
17 US\$ was calculated by multiplying the annual yield of the highest-return agricultural commodity in every
18 global agro-ecological zone (Fischer *et al*, 2000) by the average market price for that agricultural
19 commodity from 1995-2005 (<http://faostat.fao.org>). Net present value was obtained by summing annual
20 revenue over 30 years and applying a discount rate of 10%, following a different application of the same
21 data set in the Stern Review (Grieg-Gran, 2006).

22 Because the data on potential agricultural revenue was constructed using coarse global information, we
23 examined in detail the robustness of the relationship between the revenue data and deforestation (Table
24 SI10). A first-order comparison of increasing increments of \$100/ha/yr potential agricultural revenue and
25 five alternative indicators of long-term and short-term deforestation (Hansen 2006; Hansen 2008; Hansen
26 2009; Miettenen 2011; Miettenen 2012) shows that the extent of remaining forest cover is nearly
27 monotonically decreasing in potential revenue; the short-term deforestation rate and extent of palm
28 plantation are both nearly monotonically increasing in potential revenue for all but the highest increments
29 of revenue.

30 Control variables included average slope and elevation (Jarvis et al, 2008), Euclidean distance from
31 nearest national or regional roads and from provincial capitals (NGA, 2000), boundaries for 33 provinces
32 and 440 districts from the year 2003, national parks and other protected areas from the year 2006, and
33 logging concessions (HPH), timber concessions (HTI) and estate crop concessions (*kebun*) from the year
34 2005 (Minnemeyer et al, 2009). Spatial overlap between protected areas and concessions was negligible,
35 with fewer than 1% of cells containing both designations.

36 Emissions from deforestation were calculated based on the release of 100% of above- and below-ground
37 forest biomass carbon (Gibbs and Brown, 2007) plus 10% of soil carbon content in the top 30cm of non-
38 peat soil (FAO 2008). On peat soils, soil emissions were estimated based on the average 30-year non-
39 discounted emissions for the agricultural land type (large croplands; small-scale agriculture; shrublands)

40 to which such forest are converted, weighted by the area of each of these land types in historical
41 conversion across Indonesia (Hoojier, 2010). The resulting estimate of national average soil carbon
42 emissions following deforestation on peatlands was 1474 tCO₂e/ha, which compares to a tropical average
43 of 1,486±183 tCO₂e/ha calculated by Murdiyarso et al (2010). Peat extent was obtained for Sumatra
44 (Wahyunto, 2003), Kalimantan (Wahyunto, 2004) and Papua (Wahyunto, 2006), which are considered to
45 contain the vast majority of Indonesia's peat soils. Alternative biomass carbon data (WHRC, 2011) and
46 peat emission factors were explored in a sensitivity analysis (Table SI9).

47 Data were standardized into a single equal-area projection of uniform extent and gridded into 226,348
48 3km x 3km grid cells across all of Indonesia using ArcGIS 9.3.1. This grid cell resolution was chosen to
49 comply with size limitations of MS Excel. We removed grid cells for which values were missing from
50 the agricultural revenue dataset (n=25,431) or other data sets (n=5,451) leaving 195,466 grid cells
51 representing 91.8% of the land area and 95.8% of the forest area of the original data.

52

53 **Comparison of data with other published sources**

54 Observed deforestation in Indonesia from 2000-2005 was 687,000 ha/yr (Figure 1a), producing estimated
55 emissions from deforestation of 860 MtCO₂e/yr, of which an estimated 592 MtCO₂e/yr was from forests
56 on peat soil. Deforestation compares to estimates that range from 310,000 ha/yr (FAO 2010) to 703,000
57 ha/yr (Ministry of Forestry, 2008) to 1.87 million ha/yr (FAO 2005) over the 2000-2005 time period, or
58 1.1 million ha/yr in 2005 (DNPI, 2010). Emissions compare to estimates of 502 MtCO₂e/yr from
59 deforestation, of which 186 MtCO₂e/yr was associated with peat (Ministry of Forestry, 2008); 1.459
60 GtCO₂e/yr over the time period from land use, land use change and forestry (CAIT, 2010); and 1.610
61 GtCO₂e/yr emissions in 2005 from land use change, of which 770 MtCO₂e/yr was from peat (DNPI,
62 2010).

63

64 **Econometric methods**

65 We predicted site-level deforestation without carbon payments based on the relationship between the
66 observed pattern of historical deforestation and spatial variation in sites' geographic and agricultural
67 characteristics. Our empirical model builds on the theory that land-use decision makers will choose a rate
68 of conversion from forest to agriculture that maximizes the present discounted value of a future stream of
69 net benefits and costs of conversion. Given this theoretical framework we regressed percent deforestation
70 from 2000-2005 on cost and benefit variables for all 166,343 3km x 3km grid cells for which forest cover
71 was present in the year 2000 (Eq. 1). We proxied for the gross economic benefit of conversion using
72 estimated net present value of potential gross agricultural revenue. We proxied for fixed and variable
73 costs of converting forest to agriculture using a constant term and a linear combination of sites' slope,
74 elevation, natural logarithm of the distance to the nearest road, natural logarithm of the distance to the
75 nearest provincial capital, and the percent of cell contained within a national park, other protected area,
76 logging concession, timber concession, or estate crop concession, following empirical literature on
77 determinants of deforestation (e.g. Nelson and Hellerstein, 1995; Laurence et al 2002; Chomitz and
78 Thomas 2003; Pfaff et al 2007). In the absence of multi-period data on deforestation and most other

79 explanatory variables, we relied on data on changes in forest cover from a single time period. Eventually
80 multi-period data sets could be used to isolate changes in deforestation due to changes in agricultural
81 returns, infrastructure, or legal designation at particular sites. The combination of explanatory variables
82 included in the regression was selected to maximize the district-level correlation between observed and
83 predicted deforestation (Table SI7) without directly stratifying by geographic boundaries. The selected
84 variables also provided the best combination of parsimony and fit, as determined by the Akaike
85 Information Criterion (AIC) (Table SI7).

86 Recognizing that the statistical relationship between deforestation and site characteristics may vary across
87 a country as large and geographically diverse as Indonesia, we stratified sites into four classes based on
88 forest cover, with approximately 42,000 sites in each class (Table SI1). Stratifying based on a larger
89 number of forest cover classes did not improve the AIC. Explanatory variables (Table SI2) were
90 interacted with these classes in the regression.

91 We estimated the influence of explanatory variables on deforestation (Eq. 1) using a Poisson quasi-
92 maximum likelihood estimator (QMLE) (Wooldridge, 2002; Burgess et al), which is theoretically
93 consistent with 3km x 3km forest cover loss being a count of independent, discrete binary 463m x 463m
94 forest cover loss/maintenance observations from the remote sensing data. A Poisson model tolerates zero
95 values, and generates a distribution of predicted values which fits the distribution of observed data, which
96 is concentrated nearest to zero deforestation and diminishes toward greater levels of deforestation.
97 Because the data for percent deforestation is slightly overdispersed (mean=0.067; variance=0.078;
98 n=166,343), we considered a negative binomial regression, resulting in outputs that are highly correlated
99 with those of the Poisson regression (Table SI5, Table SI7). Standard errors were specified to be robust
100 to heteroskedasticity. The inclusion of spatially lagged deforestation as an explanatory variable increased
101 overall explanatory power, but had little effect on the significance or magnitude of coefficients on
102 observable site characteristics (Table SI7). Alternative functional forms, explanatory variables, and
103 stratification classes were explored to confirm robustness (Tables SI3-SI6).

104 Explanatory variables used to construct the reference scenario were significantly correlated with observed
105 deforestation, producing coefficients with expected signs and plausible magnitudes (Table SI3).
106 Consistent with results widely observed elsewhere, deforestation was found to be higher at lower and
107 flatter sites, and closer to roads and provincial capitals, controlling for other factors. Deforestation was
108 also lower in national parks and other protected areas, and higher in timber and estate crop concessions,
109 controlling for other factors. This likely reflects variation in underlying unobservable site characteristics
110 associated with the non-random allocation of these land-use designations, in addition to the impact of the
111 designations themselves (Pfaff et al, 2009). Deforestation was lower in logging concessions, controlling
112 for other factors, possibly reflecting a logging moratorium issued in May 2002, or that forest degradation
113 due to selective logging may not have been identified in our deforestation data set.

114 Potential gross agricultural revenue was significantly and positively correlated with observed
115 deforestation; this relationship was robust to the use of an alternative data set on forest cover loss (Table
116 SI6). We examined the impact of potential bias in agricultural revenue data by estimating emission
117 reductions and revenue at the high and low extremes of the 95% confidence intervals around the
118 coefficient on the effect of potential gross agricultural revenue on deforestation (Table SI9). We

119 examined the impact of potential noise in agricultural revenue data by selecting a random draw for each
120 site from the confidence interval around the same coefficient (Table SI9).

121 We used the econometric model (Eq. 1) to predict deforestation at every site in the absence of REDD+
122 (Eq. 2) (the “reference scenario”). This generates an effective land rental value for every site (Eq. 3),
123 based not only on potential gross agricultural revenues but also on our proxies fixed and variable land
124 conversion costs. We adjusted the econometric model based on hypothetical carbon payments to predict
125 deforestation at every site under a REDD+ program (Figure SI1) (Eq. 4,6).

126 **Parameter choices and sensitivities**

127 We selected a default price of 2008 US\$10/tCO₂e for ease of comparison with other studies. Our
128 estimates of abatement in response to a \$10/tCO₂e carbon price fall within the range of estimates of
129 abatement potential from REDD+ in Southeast Asia produced by global forestry and land-use models: 50
130 MtCO₂e/yr in the Generalized Comprehensive Mitigation Assessment Process Model (GCOMAP); 70
131 MtCO₂e/yr in the Dynamic Integrated Model of Forestry and Alternative Land Use (DIMA); 875
132 MtCO₂e/yr in the Global Timber Model (GTM) [7]; and 233 MtCO₂e/yr in a bottom-up model of
133 REDD+ in smallholder landscapes and fire prevention in Indonesia [20].

134 The effective elasticity parameter was calibrated so that leakage of deforested area matched estimates
135 generated by a 35-sector, 5-region general equilibrium model of the Indonesian economy (IRSA-
136 Indonesia-5; [50]), in which a 10% exogenous decrease in estate crop production in each one of five
137 regions in turn (Java/Bali; Sumatra; Kalimantan; Sulawesi; Eastern Indonesia) produced an average
138 increase in production elsewhere within the country of 18% of the initial decrease in production.
139 Variations in agricultural prices and the pressure for intranational leakage were explored in a sensitivity
140 analysis (Table SI9).

141 We tested the sensitivity of estimated impacts to a variety of policy variables (Table SI8) and model
142 parameters (Table SI9). Higher carbon prices resulted in greater abatement. We selected 20% revenue
143 sharing and 20% responsibility sharing as illustrative values in the improved voluntary incentive
144 structure. Greater levels of revenue sharing resulted in less overall abatement but augmented a
145 programmatic budget surplus, while greater levels of responsibility sharing resulted in greater
146 participation, greater overall abatement, and an augmented programmatic budget surplus. Optimal levels
147 of revenue and responsibility sharing would depend on a country’s relative preference for program
148 effectiveness and equity of distribution of revenues across scales. Scaling sub-national reference levels
149 downward uniformly from business-as-usual rates resulted in less participation and less overall abatement
150 but augmented a programmatic budget surplus.

151
152 In the absence of spatially explicit data, we proxied for potential transaction costs through three
153 sensitivity analyses (Table SI9). District-level implementation and monitoring costs diminished net
154 reductions and revenue very little, as some small districts opted out but larger districts continued to
155 participate in REDD+. On the other hand, site-level costs (e.g. those related to enforcement, management
156 or forgone logging revenue) had a stronger dampening effect on emission reductions. Governance and
157 institutional barriers, proxied through increases to local decision makers’ preference for agricultural
158 revenue relative to carbon revenue, also resulted in diminished emission reductions.

159

160 The model developed here can potentially be extended to examine a number of interesting topics beyond
161 the scope of the current analysis, including a richer suite of land-use changes (e.g. logging and forest
162 degradation; reforestation) and policy decisions (e.g. land tenure; infrastructure; agricultural subsidies and
163 taxes; conservation of biodiversity and ecosystem services).

296

297

298
 299 **Figure SI1 – Predicted site-level deforestation as a function of potential agricultural and carbon**
 300 **revenue.** Many previous studies have estimated the abatement potential of REDD+ policies based on the
 301 deterministic assumption that deforestation could be avoided entirely if and only if revenue from carbon
 302 payments exceeds income from alternative land uses (“opportunity cost approach”). We estimate the
 303 marginal impact of potential carbon payments on site-level deforestation by using a Poisson regression to
 304 determine the empirical relationship between the pattern of observed historical deforestation and spatial
 305 variation in the benefits and costs of converting forested land to agriculture (“revealed preference
 306 approach”).

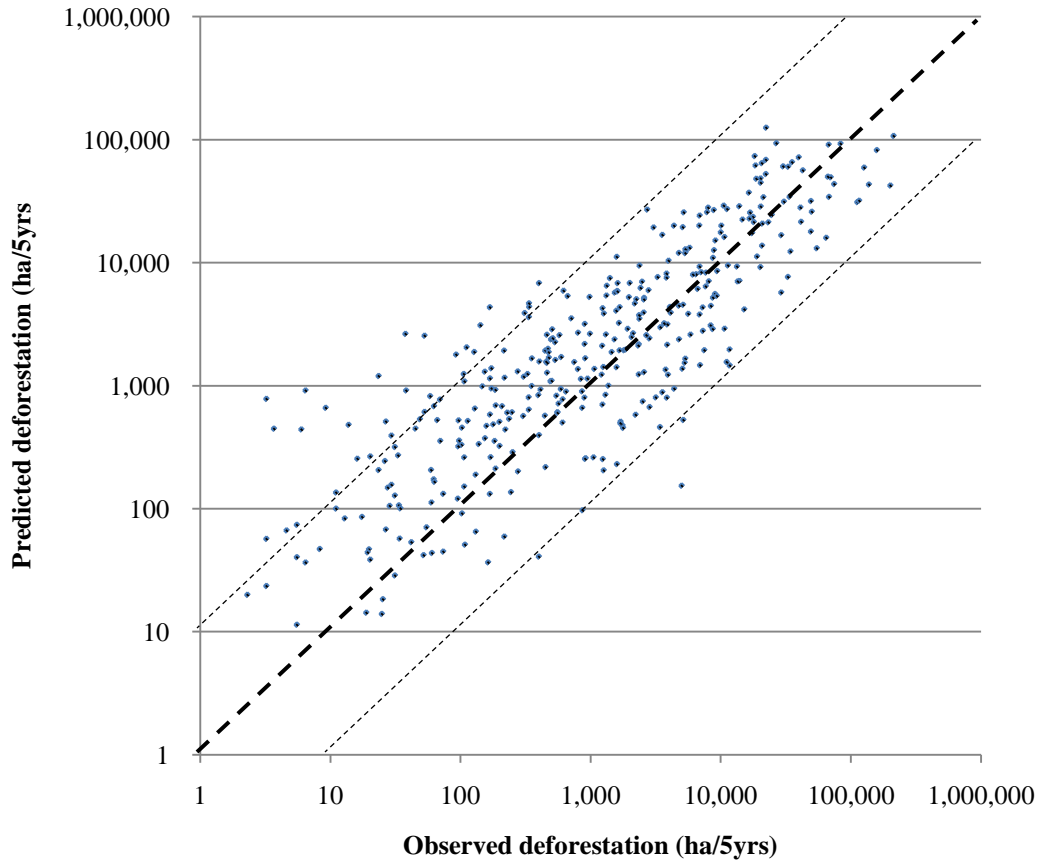

307

308

309 **Figure SI2 – District-level allocation of land between forest and agriculture.** Based on Figure 2 in
 310 Busch et al 2009. Line *a* represents the district-level supply curve for emissions-producing agricultural
 311 expansion into forest in the absence of a REDD+ mechanism. Greater potential agricultural revenue per
 312 hectare produces greater emissions from deforestation. Line *b* represents the district supply curve if the
 313 district opts into REDD+ by reducing its emissions below its reference level. This supply curve is shifted
 314 inward by the carbon payment, which is a function of the carbon price and the revenue sharing
 315 arrangement. Line *c* is the district supply curve if the district opts out of REDD+ by increasing its
 316 emissions above its reference level. This supply curve is shifted inward by the penalty, which is a
 317 function of the carbon price and the responsibility sharing arrangement. The district chooses the quantity
 318 of emissions from agricultural expansion *m* or *n* which provides greater total carbon revenue and
 319 agricultural revenue at the equilibrium agricultural price.

320

321

322 **Figure SI3 – Observed deforestation and predicted deforestation compared for forested districts of**
 323 **Indonesia, 2000-2005. (n=401; R=0.68)** Predicted deforestation using model specification 1 (Poisson;
 324 stratified by forest cover). Heavy dotted 45° line indicates predicted deforestation equal to observed
 325 deforestation within a district. Light dotted lines indicate the boundaries within which predicted
 326 deforestation is within a factor of ten of observed deforestation.

327

328 **Equations**

329

330 Eq. 1 – Predicted deforestation at sites in the absence of REDD+ based on observable site characteristics

$$y_i = \exp(\beta_{k0} + X_i' \beta_{k1} + \beta_{k2} A_i + \epsilon)$$

331 Here $y_i = (F_i^o - F_i')/F_i^o$ is percent deforestation at site i , where F_i^o is forest cover at site i at the start of
 332 the 2000-2005 observation period, and F_i' is forest cover at site i at the end of the observation period.
 333 $k \in 1:4$ are classes of observations stratified by initial forest cover (Table SII). X_i is a matrix of
 334 observable site characteristics, including slope, elevation, natural logarithm of the distance to the nearest
 335 road, natural logarithm of the distance to the nearest provincial capital, and the percent of site within a
 336 national park, other protected area, logging concession (HPH), timber concession (HTI), or estate crop
 337 concession (*kebun*). A_i is the net present value of gross agricultural revenue potential per hectare at site i .
 338 The term β_{k0} captures unobserved constant components of the expected net benefits of deforestation.

339

340 Eq. 2 – Expected deforestation at sites in the absence of REDD+

$$\hat{y}_{i-without REDD+} = \exp(\hat{\beta}_{k0} + X_i' \hat{\beta}_{k1} + \hat{\beta}_{k2} A_i)$$

341 Here $\hat{y}_{i-without REDD+}$ is the expected deforestation at site i in the absence of REDD+. The distribution
 342 across the country of all $\hat{y}_{i-without REDD+}$ is the reference scenario.

343

344 Eq. 3 – Effective land rental value at a site

$$A_i + \frac{\hat{\beta}_{k0} + X_i' \hat{\beta}_{k1}}{\hat{\beta}_{k2}}$$

345 Effective land rental value at a site includes not only potential gross agricultural revenue but also costs.

346

347 Eq. 4 – Expected deforestation at a site in a district that opts in to REDD+

$$\hat{y}_{i-with REDD+; opt in} = \exp(\hat{\beta}_{k0} + X_i' \hat{\beta}_{k1} + \hat{\beta}_{k2} ((1 + \tau_1 + \tau_2) A_i - R_i))$$

348 Here τ_1 is the endogenous increase in price due to intranational leakage, and τ_2 is the exogenous increase
 349 in price due to international leakage. R_i is the marginal carbon revenue per hectare of forest accruing to a
 350 district that has opted in to REDD+.

351

352 Eq. 5 – Carbon revenue per hectare of forest accruing to a district which has opted in to REDD+

$$R_i = p_C * (1 - r) * E_i$$

353 Here p_C is the price paid by international buyers for carbon emission reductions, $r \in [0,1]$ is the portion
 354 of world carbon price withheld by the national government under a revenue sharing arrangement (e.g. $r=0$
 355 world signify that carbon price accrues entirely to the district), and E_i is the emission reductions resulting
 356 from a decrease in deforestation at parcel i (tCO₂e/ha).

357

358 Eq. 6 – Expected deforestation at a site in a district that opts in to REDD+

$$\hat{Y}_{i-with REDD+; opt out} = \exp(\hat{\beta}_{k0} + X_i' \hat{\beta}_{k1} + \hat{\beta}_{k2}((1 + \tau_1 + \tau_2)A_i - C_i))$$

359 Here C_i is the marginal cost per hectare of deforestation incurred by a district which has opted out of
 360 REDD+.

361

362 Eq. 7 – Cost per hectare of deforestation incurred by a district which has opted out of REDD+

$$C_i = p_C * (1 - l) * E_i$$

363 Here $l \in [0,1]$ is the share of cost for emission increases borne by the national government under a
 364 responsibility-sharing arrangement (e.g. $l=1$ would signify that cost is borne entirely by the national
 365 government).

366

367 Eq. 8 – Districts' participation decision

$$p_C * (1 - r)[RL_j - \sum_{i \in j} (\hat{Y}_{i-with REDD+; opt in} * F_i^o * E_i)] >$$

$$369 \quad \gamma[\sum_{i \in j} (\hat{Y}_{i-with REDD+; opt out} - \hat{Y}_{i-with REDD+; opt in}) * F_i^o * (1 + \tau_1 + \tau_2) * A_i]$$

$$- p_C * (1 - l) * \sum_{i \in j} (\hat{Y}_{i-with REDD+; opt out} * F_i^o * E_i - RL_j)$$

370 Here RL_j is the reference level for district j , and F_i^o is the starting forest cover at site i . Parameter γ
 371 represents the district's preference for agricultural revenue relative to carbon revenue.

372

373 Eq. 9 – Expected aggregate deforestation within a district, without REDD+

$$D_{j,without REDD+} = \sum_{i \in j} (\hat{Y}_{i-without REDD+} * F_i^o)$$

374

375 Eq. 10 – Expected aggregate deforestation within a district, with REDD+

$$D_{j,with REDD+} = \sum_{i \in j} (\hat{Y}_{i-with REDD+} * F_i^o)$$

376

377 Eq. 11 – Expected aggregate emissions within a district, without REDD+

$$E_{j,without REDD+} = \sum_{i \in j} (\hat{Y}_{i-without REDD+} * F_i^o * E_i)$$

378

379 Eq. 12 – Expected aggregate emissions within a district, with REDD+

$$E_{j,with REDD+} = \sum_{i \in j} (\hat{Y}_{i-with REDD+} * F_i^o * E_i).$$

381

382

383 Eq. 13 – Expected carbon revenue accruing to district from opting in to REDD+

$$B_j = \max \{0, (RL_j - E_{j,with REDD+}) * p_c * (1 - r)\}.$$

385

386

387 Eq. 14 – Expected cost incurred by a district from opting out of REDD+

$$C_j = \max \{0, (E_{j,without REDD+} - RL_j) * p_c * (1 - l)\}$$

388

389

390 Eq. 15 – Expected aggregate deforestation nationwide, without REDD+

$$D_{without REDD+} = \sum_j D_{j,without REDD+}$$

391

392

393 Eq. 16 – Expected aggregate deforestation nationwide, with REDD+

394

$$D_{with REDD+} = \sum_j D_{j,with REDD+}$$

395

396

397 Eq. 17 – Endogenous increase in potential agricultural revenue due to decreased aggregate deforestation
398 nationwide

$$\tau_1 = \left(\frac{D_{without REDD+}}{D_{with REDD+}} \right)^e$$

399 The “effective elasticity” parameter e is functionally equivalent to the price elasticity of demand for
400 frontier agriculture, but is calibrated to also incorporate economy-wide feedbacks in the domestic labor
401 and productive capital markets from the separate IRSA-5 general equilibrium model of the Indonesian
402 economy.
